[1] The purpose of this work is to investigate the direct radiative forcing of aerosols over the supersite of Djougou (northern Benin) during the African Monsoon Multidisciplinary Analyses dry season experiment. We focus our simulations on the top of atmosphere, bottom of atmosphere, and atmosphere radiative forcings. During the dry season period, Sun photometer measurements indicate a rather turbid atmosphere with a mean aerosol optical depth for the overall period of 0.78 ± 0.24 (at 440 nm). The aerosol absorption coefficient estimated at the surface ranged between 2.3 and 37.3 Mm^{-1} (mean value $15.2 \pm 10.6 \text{ Mm}^{-1}$ at 520 nm) and the scattering coefficient between 44.5 and 232.3 Mm^{-1} (mean $145 \pm 59 \text{ Mm}^{-1}$ at 520 nm). This leads to a single scattering albedo of between 0.81 and 0.98 (at 520 nm) with a mean (and standard deviation) value of 0.91 ± 0.05 , indicating moderately absorbing aerosols. In parallel, micropulse lidar measurements indicate the presence of two distinct aerosol layers, with a first one located between the surface and 1 km and a second one located above 1.5–4.0 km. On the basis of surface and aircraft observations, sunphotometer measurements, lidar profiles, and Moderate Resolution Imaging Spectroradiometer sensor an estimation of the daily clear sky direct radiative forcing has been estimated for the 17–24 January 2006 period. Simulations indicate that aerosols reduce significantly the solar energy reaching the surface (mean $\Delta F_{\text{BOA}} = -61.5 \text{ W/m}^2$) by reflection to space (mean $\Delta F_{\text{TOA}} = -18.4 \text{ W/m}^2$) but predominantly by absorption of the solar radiation into the atmosphere (mean $\Delta F_{\text{ATM}} = +43.1 \text{ W/m}^2$). The mean heating rate at the surface and within the elevated biomass burning layer is considerably enhanced by 1.50 and 1.90 K day^{-1} , respectively.

1. Introduction

[2] Although atmospheric aerosols are recognized to be a crucial agent of climate change [*Intergovernmental Panel on Climate Change (IPCC)*, 2007], the estimation of their impact on climate remains an important scientific challenge. Indeed, in contrast with the radiative forcing attributed to greenhouse gases, which may be determined to a reasonably high degree of accuracy, the uncertainties related to aerosol radiative forcings remain very large [*IPCC*, 2007]. This is in the first place because of the complexity of aerosols.

Atmospheric particles have different sources, sizes, chemical compositions, mixing, shapes, optical properties and lifetimes, which makes it difficult to get an accurate estimation of their climatic impact at regional or global scale.

[3] Among all sources of atmospheric particles around the world, Western Africa is the world's largest source of biomass burning aerosols and mineral dust. Satellite observations indicate that these aerosol plumes, characterized by high aerosol optical depths (often greater than one in the visible range) are the most widespread, persistent and dense observed at global scale. The effect of such plumes of dust and smoke aerosols on climate change represents one of the largest uncertainties in the Earth radiative budget.

[4] Atmospheric aerosols emitted in Western Africa can modify the radiative budget directly by absorption or scattering of solar radiations. Additionally, they can modify cloud microphysics and cloud lifetime when particles act as cloud condensation nuclei [*Twomey*, 1977]. Furthermore, as dust and smoke particles are able to absorb solar radiation, the radiative heating due to aerosol layers can modify

atmospheric dynamics and suppress convection, resulting in evaporation of clouds [Ackerman *et al.*, 2000]. This effect, called the “semidirect” effect, can lead to a positive forcing by reducing cloud fractional cover and counterbalancing the aerosol indirect effect. As examples, Koren *et al.* [2004] have demonstrated the reduction in cumulus cloud cover over the Amazon region during the smoke season, whereas Abel *et al.* [2005] indicate significant regional direct effect of smoke particles over the Southern African region during anthropogenic burning activities.

[5] Hence, dust and smoke particles coming from the West Africa region could strongly modify the regional or global climate as they have the potential to be exported over great distances by prevailing winds and atmospheric waves. Improved representation of their climatic effects requires, in addition to modeling exercises and satellite observations, ground-based and integrated column measurements of their physical, chemical and optical properties, associated with their vertical distribution. This specific question represents one of the objectives of the African Monsoon Multidisciplinary Analysis (AMMA) project [Redelsperger *et al.*, 2006], as few data characterizing optical properties and direct radiative forcing of aerosols in the Western Africa region are available in the literature.

[6] In this work, we present results of aerosol optical properties and direct radiative impact obtained during January 2006, in the frame of the Special Observation Period-0 (SOP-0) experiment (J. M. Haywood *et al.*, Overview of the dust and biomass-burning experiment and AMMA SOP-0, submitted to *Journal of Geophysical Research*, 2008), on the Djougou ground-based station (9.70°N/1.68°W, northern Benin), which was administered by the Laboratoire d’Aérodologie (France, Toulouse). Among all sites instrumented during AMMA, the measurements performed at Djougou represent a unique database for studying the microphysical and optical properties of expected mixed aerosols (dust and biomass burning), compared to other sites located in the Sahelian dust region, north of the main biomass burning areas (Figure 1). We focus our analysis during the dry season, as maximum emissions of

biomass burning aerosols occur during the December to February period.

[7] The estimation of the aerosol radiative forcing have been performed using the discrete ordinate Radiative Transfer Model (RTM) GAME (Global Atmospheric Model) [Dubuisson *et al.*, 1996, 2004]. Radiative transfer computations depend on several parameters such as the spectral values of solar radiation incident on the atmosphere, the spectral variation of the aerosol optical depth (AOD), single scattering albedo (SSA), asymmetry parameter (g), surface albedo, and associated vertical profiles of atmospheric (temperature, relative humidity and ozone concentration) properties.

[8] The methodology used for computing the aerosol clear sky radiative impact is described in detail by Mallet *et al.* [2006] and Roger *et al.* [2006]. Briefly, this method relies on a synergetic approach using in situ optical measurements of the aerosol associated with integrated measurements (Sun photometer, lidar, airborne, and satellite measurements) and a radiative transfer code which calculates the aerosol direct radiative forcing.

[9] In this article, the methodology used to measure absorbing and scattering coefficients is presented in section 3 and the results obtained in terms of aerosol optical properties (AOD, SSA and asymmetry parameter) and direct clear sky radiative forcing are presented in section 4.

2. Experimental Procedures

[10] During the AMMA dry season experiment, several sites (Figure 1), (Djougou (Benin), Niamey (Niger), Banizoumbou (Niger) and M’Bour (Senegal)) were equipped with in situ and remote sensing instruments for characterizing the microphysical and optical properties of dust and biomass burning aerosols, their mixing, vertical structure, transport and radiative forcings. These ground-based observations were completed by aircraft (Facility for Airborne Atmospheric Measurements BAe 146) and ultralight aircraft (LSCE/CNRS-CEA) measurements, as well as satellite (Moderate Resolution Imaging Spectroradiometer (MODIS)) observations.

Figure 2. Averaged daytime (0800–1800 UTC) of relative humidity (RH) at Djougou during the 17 January to 15 February period.

[11] Aerosol ground-based instrumentation deployed at Djougou was dedicated to characterize the chemical composition of particles and their physical (number size distribution) and optical (absorption and scattering) properties, by using, respectively, a 13-stage Dekati impactor, a Differential Mobility Analyzer (DMA) ($D_p < 0.5 \mu\text{m}$) connected to a Condensation Particle Counter (TSI model 3010), a GRIMM ($D_p > 0.5 \mu\text{m}$) optical particle counter, a multichannel Aethalometer (model AE-10, MAGEE Scientific; Berkeley, USA) and a single channel Nephelometer (model ECOTECH M9003). A pyranometer (Kipp & Zonen) has also been used to obtain the downward radiative fluxes across the shortwave wavelengths and near infrared region ($0.4\text{--}1.1 \mu\text{m}$).

[12] Associated with our ground-based instrumentation, a sunphotometer of the PHOTONS network (French part of the Aerosol Robotic Network (AERONET)) was also used to estimate aerosol microphysical and optical properties for the whole atmospheric column [Dubovik *et al.*, 2000, 2002; Dubovik and King, 2000]. Finally, over Djougou, the vertical profiles of the attenuated backscattering and extinction coefficients have been estimated from an aerosol micropulse lidar (MPL) (model CE 370–2), developed by CIMEL, which is a micropulse system operating at 532 nm [Pelon *et al.*, 2008]. Measurements are taken according to a standard sequence of 10 min acquisition every 30 min.

3. Methodology for Estimating Absorbing and Scattering Coefficients

3.1. Aerosol Absorbing Coefficient

[13] The aerosol absorption coefficient (b_{abs}) was estimated by an AE10 aethalometer. It should be noted that,

following the work of Schmid *et al.* [2006], who reported no statistically significant dependence of ambient absorbing coefficient on relative humidity (RH) (for values comprised between 40 and 80%), we do not take into account corrections of b_{abs} with RH. First, the absorbing coefficient is defined with the Beer-Lambert's law

$$I = I_0 \exp(-b_{\text{abs}}x), \quad (1)$$

where I_0 is the intensity of the incoming light and I the remaining light intensity after passing through a filter with the thickness x . The attenuation (ATN) is given as a percentage and is defined by the following relation

$$\text{ATN} = \ln(I_0/I). \quad (2)$$

The aethalometer attenuation coefficient (b_{ATN}) is defined as

$$b_{\text{ATN}} = (A/Q) \times (\Delta\text{ATN}/\Delta t), \quad (3)$$

where A is the filter spot area, Q the volumetric flow rate, and ΔATN is the change in attenuation during the interval Δt . It is well known that b_{ATN} may differ from the true aerosol absorption coefficient b_{abs} . Hence, the parameters C and $R(\text{ATN})$ are introduced by Weingartner *et al.* [2003] in order to convert aethalometer attenuation measurements to “real” absorption coefficients. The following relationship is used:

$$b_{\text{abs}} = \frac{b_{\text{ATN}}}{C \times R(\text{ATN})}, \quad (4)$$

Figure 3. Aerosol number size distribution measured from Differential Mobility Analyzer (DMA) at Djougou for the 17, 18, 19, and 21 January.

where C and R describe the two effects which modify the optical properties of filter particles. As mentioned by Weingartner *et al.* [2003], C represents corrections due to the multiple scattering of the light beam between the filter fibers, leading to enhanced light absorption of the deposited particles [Liou *et al.*, 1993]. The constant C mainly depends on the nature of the filter used. Petzold *et al.* [1997] reported values of C between 1.9 and 2.5. In this work, we used a value of 2.14 (E. Weingartner, personal communication, 2006). However, sensitivity tests have been performed and show an accuracy of $\pm 12\%$ on b_{abs} , following the value used for C .

[14] The second effect, the “shadowing effect,” is linked to the amount of aerosol particles embedded in the filter and optical properties of the deposited particles. This effect is

described through the empirical function of $R(\text{ATN})$. For unloaded filters, R is equal to 1 ($R(\text{ATN} = 0) = 1$). In case of high filter loadings, the absorbing particles in the filter are able to absorb a higher fraction of the scattered light, leading to a reduction of the optical path in the filter ($R \leq 1$).

[15] Weingartner *et al.* [2003] reported that the shadowing effect of the particles is very pronounced for “pure” soot particles while it is almost negligible for aged atmospheric aerosols. This difference at the remote site is explained by the incorporation of a high amount of scattering aerosol material, which partially compensates the shadowing effect. Hence, in this work, considering that Djougou is not located at the sources of biomass burning emissions,

Figure 4. Comparisons between DMA number size distributions measured at Djougou and onboard the BAe 146 aircraft for the passage over Djougou (19 January). Vertical bars show ± 1 standard deviation for the aircraft data and ± 1 standard deviation for the Djougou day mean.

we used $R(ATN) = 1$. The absorption coefficient is then computed as follow:

$$b_{\text{abs}} = \frac{b_{\text{ATN}}}{2.14} \quad (5)$$

3.2. Aerosol Scattering Coefficient

[16] The particle scattering coefficient (b_{neph}) was measured at 520 nm by an ECOTECH nephelometer. Air is sampled through the semi-isokinetic inlet and the sample RH is maintained below 40%. It should be noted here that corrections on the scattering coefficient due to RH have been taken into account only in case of ambient RH larger than 40% by using *Magi and Hobbs's* [2003] relations.

[17] The RH dependence on b_{scat} is generally fitted with the following empirical function:

$$b_{\text{scat}} = b_{\text{scat,dry}} \left[1 + a(\text{RH}/100)^b \right], \quad (6)$$

where b_{scat} is the light scattering at ambient RH, $b_{\text{scat,dry}}$ is the light scattering coefficient in dry state, a and b are empirical fitting parameters. At the surface, we have used the values of 2.55 ± 0.19 and 3.59 ± 0.33 , for a and b , respectively, corresponding to regional air samples obtained during SAFARI 2000 by *Magi and Hobbs* [2003]. It should be noted that this correction has been only used in few cases, as the ambient RH was generally lower than 45% (Figure 2) during the SOP-0.

[18] One of the major sources of errors from the nephelometer originates from the instrument geometrical limitations as the nephelometer cannot detect the entire phase function of the scattered light; it only measures aerosol light scattering coefficient for angular integration of 7° – 170° . Hence, the results provided by the nephelometer measurements underestimate the actual scattering coefficient. This effect has been shown to be low for submicron aerosols, whereas the errors can be higher [*Alfaro et al.*, 2003] for supermicron particles. In order to take this effect into account, the following relation is used:

$$b_{\text{scat}}(520) = b_{\text{neph}}(520) C_{\text{corr}}, \quad (7)$$

where $b_{\text{neph}}(520)$ is the dry scattering coefficient directly measured from the nephelometer at 520 nm, C_{corr} is the correction factor and $b_{\text{scat}}(520)$ is the real dry scattering coefficient.

[19] For anthropogenic aerosols, *Carrico et al.* [2000] reported a slight underestimation of the total scattering coefficient of about 4% and *Formenti et al.* [2002] reported

Figure 5. Aerosol number size distribution measured with GRIMM at Djougou during the 17–24 January period.

Figure 6. Aerosol optical depth (AOD) retrieved at 440 nm from Sun photometer measurements (PHOTON/LOA) at Djougou during the January–February 2006 period. Vertical bars show uncertainty (± 0.01) in AOD measurements.

a total correction factor (C_{corr}) ranging between 1.08 and 1.05 (450 and 700 nm) for biomass burning aerosols, characterized by a modal diameter around $0.15 \mu\text{m}$. Finally, Mallet *et al.* [2005] reported C_{corr} of 1.10 for urban/industrial submicronic aerosols.

[20] In numerous studies, C_{corr} is usually estimated from the wavelength dependence of light scattering, as measured by the TSI 3-wavelength nephelometer, based on the work of Anderson and Ogren [1998]. In case of a single channel nephelometer, as the ECOTECH one used in our study, the spectral dependence of scattering is unavailable. Consequently, in order to correct scattering coefficients at Djougou, an alternative method has been adapted. First, the aerosol size distribution has been estimated from Differential Mobility Analyzer and GRIMM analyses. Then, a correction factor deduced from the literature [Heintzenberg *et al.*, 2006] has been applied.

[21] At Djougou, the aerosol number size distribution was determined using a Vienna type medium size DMA, connected to a Condensation Particle Counter (TSI model 3010), plus a GRIMM. Results from DMA, averaged for one day, are reported in the Figure 3. We can clearly observe that number size distributions (for $D_p < 0.5 \mu\text{m}$) are monomodal during the dry season, with the presence of a fine mode around $0.1 \mu\text{m}$. It should be noted here that a good agreement (Figure 4) has been found with Passive Cavity Aerosol Spectrometer Probe (PCASP) measurements performed on board the BAe 146 aircraft for the passage over Djougou (altitude of 500 m) for 19 January. Associated with DMA, the GRIMM measurements (Figure 5) indicated two other modes, with an accumulation (mode diameter of

$0.8 \mu\text{m}$) and a coarse one (mode diameter of $2 \mu\text{m}$). However, their concentrations are significantly lower compared to the fine mode and the corrections needed on nephelometer measurements are expected to be low. Hence, we considered in this work a correction factor (C_{corr}) of 1.10 in our computations [Heintzenberg *et al.*, 2006] and we assumed a 10% error in b_{scat} [Formenti *et al.*, 2002].

4. Results and Discussion

[22] As mentioned in the introduction, radiative transfer computations depend on several aerosol optical parameters such as the spectral variation of the AOD (see section 4.1.1), SSA (see sections 4.1.2 and 4.1.3) and asymmetry parameter (see section 4.1.4). Two methods for estimating SSA are used in this study. The first one (see section 4.1.2) uses measurements of the scattering and absorption coefficients, providing SSA at one wavelength (520 nm). The second method (see section 4.1.3) uses measurements of the aerosol size distributions together with the refractive index and Mie theory. This latter method allows calculating SSA at different wavelengths. It should be noted that the effect of nonsphericity of dust leads to a low impact on the asymmetry parameter [Bellouin *et al.*, 2004], which is used as input in our radiative transfer model.

4.1. Aerosol Optical Properties

4.1.1. Aerosol Optical Depth

[23] Results of Sun photometer measurements obtained in January–February 2006 are presented in Figure 6, where daily mean AOD at 440 nm (AOD_{440}), with associated

Figure 7. Aerosol absorbing, scattering coefficient, and single scattering albedo (SSA) estimated at 520 nm from aethalometer and nephelometer measurements. Vertical bars show error (± 12 , ± 10 , and $\pm 5\%$) on the absorbing, scattering, and SSA calculations.

uncertainty in AOD [Holben *et al.*, 1998] also shown. Although a much smaller amount of mineral dust has been observed during 2006, compared to previous years, Djougou atmosphere was rather turbid with AOD_{440} exceeding 0.5 for 90% of the days during January and February. The mean (and standard deviation) AOD_{440} during this period is 0.78 ± 0.24 , indicating a significant aerosol loading. Very high AOD_{440} is observed for 17 and 18 January, with daily mean values of 1.5 and 1.1.

[24] A way to know which kind of aerosols is present is to compute the Angström exponent (α), which represents the spectral variation of AOD. This optical parameter can help to infer the aerosol type (e.g., whether it is anthropogenic or dust-like) because of the dependency of α on particle size. For coarse aerosols, such as dust, α is close to 0 and for submicron particles (such as biomass burning or urban/industrial), α is often between 1 and 2. It can be computed from the following relation:

$$\alpha \lambda_1 / \lambda_2 = -\log(AOD \lambda_1 / AOD \lambda_2) / \log(\lambda_1 / \lambda_2), \quad (8)$$

where λ_1 and λ_2 represent the wavelength range over which α is calculated. The Angström exponent is commonly computed between 440 and 870 nm. Over Djougou, the mean value of $\alpha_{440/870}$ is 1.00 ± 0.21 over the total atmospheric column. This value is found to be lower than those observed from photometer measurements for pure smoke [Dubovik *et al.*, 2002], revealing a possible mixing between fine smoke particles and mineral dust over the column. This result is in agreement with the aerosol size

distribution measured at Djougou, indicating the presence of fine and accumulation (expected to be smoke) modes [Haywood *et al.*, 2003], and a coarse mode (expected to be mineral dust).

4.1.2. Determination of Aerosol Single Scattering Albedo From Absorbing and Scattering Coefficients

[25] The absorption coefficient measured at 520 nm ($b_{abs(520)}$) is presented in Figure 7. Results show that $b_{abs(520)}$ ranged from 2.3 to 37.3 Mm^{-1} with an average (and standard deviation) for the overall period of $15.2 \pm 10.6 \text{ Mm}^{-1}$. For comparisons, b_{abs} is found to be generally lower than those observed by Chand *et al.* [2006] during the SMOCC experiment, which took place over the Amazon Basin from 16 September to 14 November in 2002. Chand *et al.* [2006] reported b_{abs} comprised between 1 and 70 Mm^{-1} (the average value was not indicated). In parallel, the average value obtained in this work is comparable to b_{abs} values obtained over the Indian Ocean during INDOEX ($16 \pm 8 \text{ Mm}^{-1}$ from Mayol-Bracero *et al.* [2002]) and significantly higher to values reported during ACE-Asia for polluted aerosols (8.6 Mm^{-1} from Anderson *et al.* [2003]) or ACE-2 (8.9 Mm^{-1} from Öström and Noone [2000]).

[26] The ambient scattering coefficient estimated at 520 nm is also presented in the Figure 7. The values from our measurements ranged from 44.5 to 232.3 Mm^{-1} , with a mean value (and standard deviation), for the overall period, of $145 \pm 59 \text{ Mm}^{-1}$. As mentioned above, this mean value is found to be lower than those reported by Chand *et al.* [2006] ($5\text{--}1435 \text{ Mm}^{-1}$) during the SMOCC experiment. In parallel, our values are found to be significantly higher than

Figure 8. Comparisons between SSA measured at the surface, onboard the aircraft, and retrieved from AERONET at Djougou for 19 January.

those obtained during different field experiments, such as CLAIRE-98 (daily mean scattering coefficient of $26 \pm 8 \text{ Mm}^{-1}$ during dust outbreaks and 10 Mm^{-1} for background level, [Formenti *et al.*, 2001]), INDOEX ($62 \pm 34 \text{ Mm}^{-1}$ [Mayol-Bracero *et al.*, 2002]), ACE-Asia (55.3 Mm^{-1} [Anderson *et al.*, 2003]), or ACE-2 ($40 \pm 17 \text{ Mm}^{-1}$ [Quinn *et al.*, 2000]).

[27] The temporal variation of ambient SSA_{520} (associated with an uncertainty of $\pm 5\%$ [Formenti *et al.*, 2002]) is reported in Figure 7. We can observe values comprised between 0.81 and 0.98, indicating high heterogeneity in SSA during the SOP-0, most probably because of variation in black carbon content of the aerosol. The mean value (and standard deviation), for the overall period, is 0.91 ± 0.05 , indicating moderately absorbing particles. It should be mentioned here that a good agreement has been observed, for the 19 January, between SSA estimated at the surface ($\text{SSA}_{520} = 0.89$) and that measured onboard the BAe 146 (Figure 8) aircraft ($\text{SSA}_{520, \text{BAe}} = 0.90$). This result indicates a good level of confidence in our optical measurements and especially on the scattering correction used in the equation (7).

[28] For comparisons, our mean value is found to be higher than the one obtained by Eck *et al.* [2003] (mean of 0.84–0.85) and Leahy *et al.* [2007] (0.85 ± 0.02) during SAFARI 2000 and Eck *et al.* [2001] ($0.82\text{--}0.85 \pm 0.03$) during the ZIMBBEE experiment. However, our value is found to be consistent with those reported by Eck *et al.*

[1998] (0.88 ± 0.05 at 440 nm) and Schafer *et al.* [2002] (median SSA between 0.89 and 0.91 at 440 nm, with a standard deviation of 0.03), or Dubovik *et al.* [2002] (0.91 ± 0.03 at 440 nm) for biomass burning aerosols in Amazonia. Furthermore, our mean value is also consistent with the one reported by Chand *et al.* [2006] (0.92 ± 0.02) during the SMOCC experiment.

4.1.3. Estimation of SSA From Number Size Distribution and Refractive Index

[29] The aerosol number size distributions measured with the DMA (Figure 3) and GRIMM (Figure 5) have been fitted with lognormal functions. According to Putaud *et al.* [2000], the equivalent mobility diameter as measured by the DMA was considered to be equal to the geometric diameter, D_p . The main characteristics (number of particles, Geometric Mean Diameter (GMD) and Geometric Standard Deviation (GSD)) of the lognormal functions for the fine mode, obtained for each day, are reported in the Table 1 (the data are not available for 20 January). The averaged values indicate a total number concentration of 6100 cm^{-3} , a GMD of $0.096 \mu\text{m}$, and a GSD of 1.87. Associated with DMA measurements, those performed from GRIMM indicate two different modes, with one in the accumulation range (diameter of $0.8 \mu\text{m}$) and another in the coarse range (diameter of $2 \mu\text{m}$) for each day studied during the SOP-0.

[30] Concerning the fine mode, these characteristics are in the same order of values obtained by Rissler *et al.* [2006] in case of smoke particles produced over the Amazonian region during the dry season (GMD of $0.092 \mu\text{m}$ and a GSD of 1.63). In terms of aerosol concentrations, Rissler *et al.* [2006] also reported a value of 5213 cm^{-3} . In the review by Reid *et al.* [2005], median diameters between 0.10 and $0.13 \mu\text{m}$ are reported for smoke from grass, savanna, cerrado, and forest burning. Finally, during the SMOCC field experiment, airborne measurements of particle size distribution have shown GMD of $0.11 \pm 0.01 \mu\text{m}$ from 69 plumes within the boundary layer [Guyon *et al.*, 2005].

[31] In addition to the aerosol number size distribution, the Mie theory requires the knowledge of the refractive index of particles. This information is not available from our measurements. Therefore, at Djougou, the imaginary part of the refractive index has been obtained by constraining SSA computed with Mie theory with SSA estimated using simultaneous measurements of absorption and scattering coefficients of particles (see the previous paragraph). In our computations, the real part of the refractive index is fixed to 1.54 [Haywood *et al.*, 2003] for the fine and

accumulation modes and 1.53 [Osborne *et al.*, 2008] for the coarse mode. Concerning the imaginary part, the value is fixed to 0.0004 [Osborne *et al.*, 2008] for the coarse mode (expected to be mineral aerosol) and we adjust this for fine and accumulation modes. As reported in the Table 1, the imaginary part of the refractive index for the fine and accumulation modes varies between 0.001 and 0.032, with a mean of 0.014 (at 520 nm). For comparison, this average value obtained at Djougou is in reasonable agreement with the one reported by Haywood *et al.* [2003] (0.018 at 550 nm) for aged biomass burning plumes.

[32] Using the aerosol size distribution and refractive index, SSA has been computed at the seven wavelengths (Table 2) used in the GAME radiative transfer model. The values reported in Table 2 show no significant dependence of SSA with wavelengths, a result that is similar with the SSA spectral variation observed from AERONET retrievals. In parallel, it should be noted that comparisons between SSA estimated at the surface (at 440 nm) and those retrieved from AERONET show large differences (Table 2 and Figure 8), with AERONET retrievals generally smaller. Such differences are due to the presence of the elevated biomass burning layer, characterized by lower SSA (B. Johnson *et al.*, Aircraft measurements of biomass-burning aerosols over West Africa during DABEX, submitted to *Journal of Geophysical Research*, 2007). In this work, we took advantage of SSA obtained from in situ measurements (at the surface and in the BBL) for calculating a column mean by weighting the run means by the contribution of each layer to the total aerosol optical depth. This method provides better comparisons with AERONET, especially for the 21–24 January period (Table 2), with column mean values around 0.90 at 440 nm (SSA from AERONET is about 0.85–0.87).

4.1.4. Aerosol Asymmetry Parameter

[33] The asymmetry parameter has been computed at different wavelengths from Mie theory following the same methodology described above for SSA. As shown in the Table 3, the asymmetry parameter varied between 0.64 and 0.67 range (at 520 nm), with a mean (and standard deviation) of 0.66 ± 0.01 . As observed for SSA, no significant dependence of g with wavelengths is noted and agreement is found with AERONET observations. When we calculate g for the whole atmospheric column (as mentioned above for SSA), comparisons are found consistent with a mean of 0.64 and 0.69 (at 440 nm) from in situ and AERONET calculations, respectively. Finally, it should be noted that

our calculations are consistent with those reported by Procopio *et al.* [2004] for smoke aerosols with values ranging from 0.64 to 0.67 (at 440 nm).

4.2. Radiative Forcing

[34] The clear sky direct radiative forcing over Djougou has been estimated from the GAME radiative transfer model, detailed by Dubuisson *et al.* [2004]. GAME accounts for the scattering and absorption processes by particles and gases. Gaseous absorption (H_2O , CO_2 , O_2 , and O_3) is treated from the correlated k distribution, using a line by line code [Dubuisson *et al.*, 1996] and multiple scattering effects are treated using the Discrete Ordinates Method (DOM) [Stamnes *et al.*, 1988]. This method allows accurate treatment of scattering and absorption by aerosols, clouds, and molecules.

[35] Upward and downward net radiative fluxes are calculated over the solar spectrum, ranging from 2500 to 50000 cm^{-1} , with a 100 cm^{-1} spectral resolution. Calculations of radiative fluxes integrated over the entire short-wave region are performed at every 1 h interval and for a 24 h period. From these fluxes, we computed the aerosol clear sky daily direct forcing at the bottom of atmosphere (BOA), ΔF_{BOA} , and at the top of the atmosphere (TOA) (70 km in this case), ΔF_{TOA} . The first one represents the effect of particles on the net short-wave radiation fluxes reaching the surface and the second one the radiation fluxes reflected back to space by aerosols. BOA and TOA forcings have been calculated as following:

$$\begin{aligned}\Delta F_{\text{BOA}} &= F_{\text{BOA}(w)} \downarrow - F_{\text{BOA}(o)} \downarrow \\ \Delta F_{\text{TOA}} &= -(F_{\text{TOA}(w)} \uparrow - F_{\text{TOA}(o)} \uparrow),\end{aligned}\quad (9)$$

where $F_{\text{BOA}(w)} \downarrow$ and $F_{\text{BOA}(o)} \downarrow$ are, respectively, the downward net radiative fluxes simulated at the surface with (w) and without (o) aerosols. $F_{\text{TOA}(w)} \uparrow$ and $F_{\text{TOA}(o)} \uparrow$ are, respectively, the upward net radiative fluxes simulated at the top of atmosphere with (w) and without (o) aerosols. With this convention, a negative sign of ΔF implies an aerosol cooling effect. Finally, as reported by Roger *et al.* [2006], we compute the atmospheric forcing, ΔF_{ATM} , by using the following relation:

$$\Delta F_{\text{ATM}} = \Delta F_{\text{TOA}} - \Delta F_{\text{BOA}} \quad (10)$$

Table 3. Aerosol Asymmetry Parameter Estimated at the Surface (at Different Wavelengths) From Mie Theory and for the Whole Atmospheric Column From AERONET Retrievals

ΔF_{ATM} represents the possible absorption of solar radiation due to absorbing particles within the atmospheric specified aerosol layers.

4.3. Aerosol Vertical Profiles

[36] As reported by *Ganguly and Jayaraman* [2006], an important point for estimating the direct forcing of aerosols is their vertical profile within the atmosphere. Indeed, numerous studies [*Haywood and Ramaswamy*, 1998; *Chung et al.*, 2005] indicate that one major contributor to the uncertainty in atmospheric forcing comes from uncertainty in the vertical distribution of aerosols. Differences in vertical profiles affect the distribution of forcing within the atmosphere and can produce different patterns in terms

of cooling or heating depending on the altitude of the different aerosol layers.

4.3.1. Vertical Profiles of Aerosol Extinction Coefficient

[37] In order to take into account the vertical profiles of aerosol extinction in GAME, we have used a MPL, operating at Djougou and administered by the Service d'Aéronomie (SA). Once corrected from signal saturation and geometrical factor, the attenuated profiles are inverted to retrieve extinction coefficient profiles, α_e at 532 nm [*Pelon et al.*, 2008]. Figure 9 shows an example of extinction coefficient (in km^{-1}) profiles obtained at Djougou for 21 January (the shape of the vertical profile is similar to those obtained during all of SOP-0, *Pelon et al.* [2008]). The first aerosol layer is around 0.5 km and characterized by extinction coefficients

**Figure 9.** Profile of micropulse lidar aerosol extinction coefficient obtained at Djougou for 21 January 2006.

Table 4. Dry Mie-Derived Single Scattering Albedo and Asymmetry Parameter as Reported by B. Johnson et al. (submitted manuscript, 2007) From BAe 146 Aircraft Measurements

	Wavelengths (nm)		
	450	550	670
SSA	0.86	0.84	0.81
g	0.62	0.57	0.49

around 0.15 km^{-1} , following by a rapid decrease of α_e between 0.5 and 1 km. Above 1 km, we can observe a second aerosol layer, with α_e of 0.3 km^{-1} , for altitudes comprised between 1500 and 4000 m, assumed to be composed mainly of biomass burning aerosols (B. Johnson et al., submitted manuscript, 2007). MPL measurements show clearly the significant contribution of the biomass burning layer (BBL) to the total AOD (around 70%) and the smaller contribution of the lower aerosol layer to the total AOD (around 30%), indicating that a large part of the solar extinction at Djougou is due to the BBL.

4.3.2. Vertical Profiles of Aerosol SSA and g

[38] Associated with the aerosol extinction profiles, SSA and g vertical profiles were obtained by combining our measurements at the surface with aircraft observations and data from the literature. Briefly, the spectral variation of SSA and g computed at the surface (Tables 2 and 3) are used as input for the first aerosol layer. Concerning the BBL, we considered the spectral variation of dry SSA and g obtained onboard the BAe 146 by (B. Johnson et al., submitted manuscript, 2007) for biomass burning aerosols. These estimates have been obtained by using TSI nephelometer and Particle Soot Absorption Photometer (PSAP) measurements, for estimating scattering and absorption coefficients. In addition, Mie calculations have been also used to derive extinction coefficients, asymmetry parameters and angstrom exponents. Optical properties reported by (B. Johnson et al., submitted manuscript, 2007) for aged biomass burning aerosols and used as input in GAME are shown in the Table 4. Finally, to complete the vertical stratification, the spectral variation of optical properties coming from the aerosol models described by Hess et al. [1998] has been used for the free troposphere and stratosphere.

[39] As reported in section 3, no corrections on optical and microphysical properties due to RH have been taking into account in the lower aerosol layer (expected for RH larger than 40%). Concerning the BBL, aircraft measurements indicate that RH higher than 50% has been observed (as shown in the Figure 10 for 19 January). In such cases, dry optical properties (in particular scattering) need accurate corrections to take into account variations with RH. In our calculations, these corrections have been made for all cases by using the values of a and b (relation 6) from Magi and Hobbs [2003] for ambient smoke samples ($a = 1.31$ (0.08 and $b = 4.88$ (0.28))). As an example of results, for 19 January, dry to wet SSA changes from 0.86 to 0.90 (at 450 nm).

[40] Finally, in order to correct the asymmetry parameter with RH in the BBL, we have used the microphysical properties (GMD = $0.24 \mu\text{m}$ /GSD = 1.30) and refractive index ($1.54-0.035i$) reported in dry state by B. Johnson et

al. (submitted manuscript, 2007). GMD has been calculated in the ambient state from a growth factor of 1.24 [Rissler et al., 2006], corresponding to moderately hygroscopic biomass burning aerosols observed in South America (during the dry season). To finalize our Mie computations, the refractive index has been computed at ambient RH using the relation described by Mallet et al. [2003]. As an example of results, our calculations indicate a change in g from 0.58 (at 550 nm) in dry state to 0.65 at 85% RH for 19 January.

4.4. Vertical Profiles of Atmospheric Properties

[41] RH and temperature vertical profiles used in GAME have been measured onboard the BAe 146 aircraft for 19 January. We completed the stratification, for altitudes greater than 4 km, by using data available in the Shadoz network [Thompson et al., 2003]. Ozone concentration profiles have been determined by combining ground-based measurements performed at Djougou with the Shadoz [Thompson et al., 2003] measurements carried out on Cotonou (Southern Benin) for the upper atmosphere.

4.5. Surface Albedo

[42] As the estimation of radiative forcing has been performed over land, surface reflection is an issue. As reported by Roger et al. [2006], we used the MODIS albedo product (MODIS/Terra Albedo; 16-Day; Level-3 Global 1 km SIN Grid), which provides the spectral dependence of surface albedo over seven wavelength bands. Such information has been used as input in GAME to reproduce the surface albedo for the entire shortwave range. In our computations, a constant surface albedo has been considered for the whole month of January 2006. At 550 nm, the surface albedo at Djougou is equal to 0.20 ± 0.06 .

4.6. Error Budget

[43] Here we performed some sensitivity tests (summarized in Table 5), considering uncertainties on aerosol optical properties (for the two aerosol layers), together with the surface albedo. We apply $\pm 5\%$ on the SSA, g and

Figure 10. Relative humidity profile obtained from the BAe 146 aircraft on 19 January.

Table 5. Error Budget (Simulated at Noon) on the Determination of the Aerosol Direct Forcing Including Optical Parameters of Aerosols as Measured at the Surface and in the Biomass Burning Layer and the Surface Albedo

	$\Delta F_{\text{BOA}} (\%)$	$\Delta F_{\text{TOA}} (\%)$	$\Delta F_{\text{ATM}} (\%)$
SSA surf $\pm 5\%$	2.3	3.2	3.2
SSA BBL $\pm 5\%$	7.3	24	12.7
g surf $\pm 5\%$	0.5	1.9	0.3
g BBL $\pm 5\%$	2.3	11.5	0.7
Surface Albedo $\pm 5\%$	0.4	9.1	1.8

surface albedo. Results of induced uncertainties are given in percentage in Table 5, showing values comprised between 0.5 and 7%, 3.2 and 24%, 0.3 and 12.7% for BOA, TOA, and atmosphere (ATM) forcings, respectively. As mentioned by *Roger et al.* [2006], the overall interpretation of all these uncertainties needs to account for the linked errors and counterbalancing effects. Consequently, we can reasonably consider that the daily radiative impacts of aerosols are defined here with an accuracy of 10% for BOA, 40% for TOA, and 15% for ATM. It should be noted that uncertainties reported here are larger (especially at TOA) than those obtained by *Roger et al.* [2006] because of the presence of the BBL (Table 5).

4.7. Bottom of Atmosphere Direct Radiative Forcing

[44] As shown in Figure 11, the downward fluxes simulated at the surface by GAME compared well with pyranometer measurements performed at Djougou. The normalized bias (in percentage) is equals to -0.2% associated with a root mean square (RMS) of 25.6. As summarized in Table 6, our simulations indicate important surface radiative forcings for each day studied, with ΔF_{BOA} (and associated errors) varying between -43.8 ± 4.4 and $-84.1 \pm 8.4 \text{ W/m}^2$. Our simulations allow investigating the surface

forcing during 17 and 18 January with high AOD (1.5 at 440 nm). For these specific days, the instantaneous surface forcing estimated by GAME can reach up to -240 W/m^2 and -165 W/m^2 , for 17 and 18 January, respectively (for a solar zenith angle of 30°). Such values are found to be very consistent with observations reported by *Schafer et al.* [2002] for biomass burning aerosols in the Zambian Savanna ($\text{AOD} = 1$), with a reduction in total irradiance at the surface of 210 W/m^2 (mean solar zenith angle of 31°).

[45] In order to extend our simulations for a more representative period, we have used the mean BOA forcing efficiency (Table 6), obtained between 17 and 24 January, with AOD measured during all the dry season (Figure 6). Results are indicated in the Figure 12. The mean (and standard deviation) value obtained during the dry season period is $-45 \pm 14 \text{ W/m}^2$. For comparisons, the calculated daily surface forcing at Djougou is found to be consistent with those simulated by *Procopio et al.* [2004], who reported monthly averaged values (during the dry season) ranging from -21 to -74 W/m^2 for two locations in the Amazon region (Alta Floresta and Abracos Hill), heavily impacted by biomass burning aerosols. Our simulations are found to be comparable with those obtained during INDOEX (-45 W/m^2) by *Ramanathan et al.* [2001] and *Léon et al.* [2002].

[46] It is clear that such significant decrease of solar energy at the surface can strongly modify the surface energy budget. Indeed, under normal conditions, surface radiation flux is balanced by latent heat and sensible heat fluxes from the surface. In order to compensate for the reduction of surface solar flux, a decrease in heat flux from the surface may be expected. *Feingold et al.* [2005] and *Jiang and Feingold* [2006] have showed that the reduction in surface latent and sensible heat fluxes associated with biomass burning impact may reduce cloudiness over the Amazonia region. Consequently, and because of our high BOA values,

Figure 11. Comparison of observed versus modeled surface fluxes over Djougou.

Table 6. AOD (at 440 nm); Daily Clear Sky ΔF and Daily Efficiency ΔFE Direct BOA, TOA, and ATM Forcings; and Heating Rates Only due to Aerosols in The First Aerosol Layer (Averaged Between 0 and 1000 m) and in the BBL (Averaged Between 1500 and 4000 m)^a

it is important to study the impact of aerosols on the surface energy budget over the West African region.

4.8. TOA and Atmospheric Direct Radiative Forcing

[47] GAME calculations of upward fluxes have been compared with broad band radiometer (BBR) flux measurements performed on board the BAe 146 aircraft for 19 January and satisfactory agreements have been obtained between the normalized upward fluxes simulated with GAME ($146 W/m^2$) and the one measured from the aircraft radiometer ($140 W/m^2$), for a solar angle of 30° (1200 UTC). At Djougou, moderate or low ΔF_{TOA} (Table 6) have been computed by GAME between 17 and 24 January, with values (and associated error) between -14.8 ± 5.9 and $-23.2 \pm 9.3 W/m^2$. The mean value (and standard deviation)

is about $-18.4 \pm 3.1 W/m^2$. After averaged during all the dry season (Figure 12), the TOA forcing indicates a mean (and standard deviation) value of $-13.6 \pm 4.2 W/m^2$. For comparison, this value is found to be consistent with those obtained by Ross *et al.* [1998] ($-8 \pm 9 < \Delta F_{TOA} < -20 \pm 7 W/m^2$) for the 1995 dry season in Amazonia, and slightly larger than those ($-5 < \Delta F_{TOA} < -12 W/m^2$) reported by Procopio *et al.* [2004].

[48] One of the most important results of this study concerns the large atmospheric forcings obtained at Djougou due to significant differences between ΔF_{TOA} and ΔF_{BOA} . Our results indicated that ΔF_{TOA} is 3.5 times lower than the mean ΔF_{BOA} . During the dry season (Figure 12), ΔF_{ATM} (and associated errors) ranged from 13.1 ± 1.9 to $60.9 \pm 9.1 W/m^2$, with a mean value (and standard deviation)

Figure 12. Aerosol clear sky daily direct radiative forcing (in W/m^2) estimated for 1 January to 30 February period at Djougou. Vertical bars show error (± 12 , ± 20 , and $\pm 16\%$) on the BOA, TOA, and ATM forcings [Roger *et al.*, 2006].

Figure 13. Mean vertical profiles of the predicted heating rate due only to the presence of aerosols between 17 and 24 January.

tion) of $31.4 \pm 10.0 \text{ W/m}^2$. Our results are consistent with those reported by *Procopio et al.* [2004], with ΔF_{ATM} ranging from 16.2 to 61.7 W/m^2 .

[49] As mentioned by *Ganguly and Jayaraman* [2006], although the large difference between the BOA and TOA forcing may indicate the absorption of solar radiation in the atmosphere, it is of great importance to investigate how this atmospheric heating is vertically distributed in the atmosphere. Indeed, several studies have shown that the atmospheric heating by absorbing particles may evaporate low-level clouds, resulting in a decrease of cloud cover and planetary albedo [*Hansen et al.*, 1997; *Ackerman et al.*, 2000]. For that purpose, vertical profile of the heating rate (HER in K day^{-1}) has been computed from GAME, as described by *Roger et al.* [2006]. The average vertical profile of the predicted HER, due only to the presence of aerosols, is reported in Figure 13 and the corresponding mean HER values, for the two main aerosol layers are indicated in the Table 6.

[50] Figure 13 indicates the averaged HER computed for the period 17–24 January. Simulations show that HER decreases very sharply above 200 m to reach low values at 1 km. Above 1 km, the aged biomass burning aerosol considerably increases the average heating rate in the layer between 1.5 and 4 km altitude. Simulations indicate that HER due to aerosols varies between 0.66 and 2.20 K day^{-1} (mean value 1.50 K day^{-1}) in the first aerosol layer (Table 6) and between 1.29 and 3.27 K day^{-1} in the BBL (mean of 1.90 K day^{-1}). HER in the BBL reaches up to 3.27 K day^{-1} for 17 January. For comparison, *Keil and Haywood* [2003] observed that biomass burning aerosols increase HER by 1.77 K day^{-1} in the BBL (1.8–3.7 km) during SAFARI 2000. *Keil and Haywood* [2003] also indicate that HER can reach up to 2.05 K day^{-1} for a SSA of 0.86. These values are found to be very consistent with the one obtained from

our GAME simulations (1.91 K day^{-1}) performed at Djougou.

5. Conclusion

[51] The purpose of this work was to investigate the clear sky direct radiative forcing of aerosols over the ground-based station of Djougou, located in Northern Benin, during the AMMA dry season experiment (January–February 2006). The results presented in this work are based on ground-based measurements for estimating aerosol optical (scattering and absorption coefficients) and physical (number size distribution) properties. Additionally, we used the UK BAe 146 aircraft, PHOTON Sun photometer, micro pulse lidar and MODIS observations for estimating, respectively, vertical profiles of thermodynamic parameters, spectral variation of the aerosol optical depth (AOD), aerosol extinction vertical profiles and surface albedo. All this information has been used as input in the discrete ordinate radiative transfer model GAME, for computing the clear sky direct radiative forcing of aerosols.

[52] During this period, Sun photometer measurements indicate a mean AOD of 0.78 ± 0.24 (at 440 nm), indicating a significant aerosol loading over Djougou. The average aerosol absorption and scattering coefficients at the surface are equal to 15.2 and 145.3 Mm^{-1} (at 520 nm) respectively, leading to a mean (and standard deviation) single scattering albedo of 0.91 ± 0.05 over the period studied. At the same time, the aerosol number size distribution is shown to be composed by three modes, with a fine (characterized by a mean geometric diameter of 0.096 μm), an accumulation (mode diameter of 0.8 μm) and a coarse (mode diameter of 2 μm) mode.

[53] In addition to ground-based observations, vertical profiles of aerosol extinction coefficient have been investi-

gated through a micropulse lidar (MPL). Our results indicate a complex vertical structure, characterized by the presence of two distinct aerosol layers, with a first one located between the surface and 1 km and a second elevated layer (1.5–4.0 km). Furthermore, lidar profiles indicate also that the majority of the solar extinction over Djougou is due to the second aerosol layer, composed in majority by smoke particles, which contribute 70% of the total AOD.

[54] Our radiative transfer simulations performed between 17 and 24 January indicate that aerosols at Djougou lead to a significant diurnal average (and standard deviation) reduction of $61.5 \pm 12.9 \text{ W/m}^2$ in the surface solar radiation, an increase of $43.1 \pm 10.5 \text{ W/m}^2$ in the atmospheric solar absorption, and an increase of $18.4 \pm 3.1 \text{ W/m}^2$ in the reflected solar radiation at the top of atmosphere. In order to extend our simulations, we have used the mean BOA, TOA, and ATM forcing efficiency (obtained during 17–24 January), with AOD measured during all the dry season. Averaged over the whole dry season, our results indicated mean values of -45.0 , -13.6 , and $+31.4 \text{ W/m}^2$ for BOA, TOA, and ATM forcings, respectively, which is consistent with calculations performed for smoke aerosols in the Amazonian region.

[55] Changes in heating rates due to the presence of aerosols have been also investigated and discussed. The results we obtained indicate that the heating rates within the BHL and BBL are considerably enhanced, with a mean value of 1.50 and 1.90 K day^{-1} , respectively. Regarding such radiative forcings and changes in heating rates, future work is now clearly required for investigating the possible impact on the surface-atmosphere system during the dry season over the West African region.

[56] **Acknowledgments.** On the basis of a French initiative, AMMA was built by an international scientific group and is currently funded by a large number of agencies, especially from France, UK, US, and Africa. It has been the beneficiary of a major financial contribution from the European Community's Sixth Framework Research Programme. AMMA has been endorsed by IGBP (IGAC, ILEAPS) and WCRP (GEWEX, CLIVAR). Detailed information on scientific coordination and funding is available on the AMMA International web site (<http://www.amma-international.org>). We would like also to thank the PHOTON staff for the data collection, calibration, and processing and especially the PHOTON PIs D. Tanre (LOA) and L. Blarel (LOA). FAAM is jointly funded by the Met Office and the Natural Environment Research Council.
